Electronic structure and magnetic properties of scandium*

Shashikala G. Das
Argonne National Laboratory, Argonne, Illinois 60439
(Received 19 June 1975)

The Van Vleck orbital and Pauli spin paramagnetic contributions to the magnetic susceptibility of single-crystal and polycrystalline scandium are calculated using the augmented-plane-wave method in conjunction with a linear-combination-of-atomic-orbitals interpolation scheme, which uses $s$, $p$, and $d$-type functions in the tight-binding representation. The warped-muffin-tin potential was obtained from overlapping charge densities, which were derived from the atomic configuration $3d^{7}4s^{1}$; the exchange interaction was included in full Slater $\rho^{1/3}$ approximation. The Fermi energy is found to lie in a sharp peak in the density-of-states curve. The anisotropy in the magnetic susceptibility and the low-temperature variation of the susceptibility of scandium, particularly the hump around 25°K observed by Spedding and Croat, are successfully explained. The large enhancement of the low-temperature specific heat due to spin fluctuations calculated from the molecular-field parameter in random-phase approximation is shown to account for the absence of superconductivity in scandium.

I. INTRODUCTION

Scandium, having one electron in the $3d$ shell, is the first of the series of transition metals and does not have the unpaired $4f$ electrons unlike other rare earths, to swamp the temperature dependence of magnetic susceptibility $x$ arising from the Pauli spin paramagnetism and the orbital paramagnetism of $d$ electrons. Therefore, information concerning the electronic structure of Sc in the metallic state and also some of its intermetallic compounds is of fundamental interest for the clarification of the role of $d$ electrons in the transition metals. Although the magnetic susceptibility of scandium has been measured by several groups,¹ neither the value of $x$ nor its temperature dependence was accurately known until the recent measurements of Spedding and Croat¹ on highly pure Sc were available. These measurements have also shown a previously unobserved maximum around 25°K in the single-crystal and polycrystalline susceptibility of Sc, which disappears as small amounts of impurities are added. This peak could not be explained, as there is no antiferromagnetic ordering in Sc around that temperature.² Although the band structure of scandium has been studied previously,³⁴⁵ to our knowledge, until very recently⁶ information on wave functions near the Fermi level, essential to the understanding of these phenomena in Sc, was scarce and incomplete. Based on a tight-binding linear-combination-of-atomic-orbitals (LCAO) scheme,⁷ we present here results for the projected and total density of states (DOS), the magnetic susceptibility, and in particular explain the maximum in the $x$ vs $T$ curve around $T \approx 25$°K. In Sec. II we discuss the procedural details, and in Sec. III we present the results of our calculations.

II. PROCEDURAL DETAILS

The energy eigenvalues for the high-symmetry points were calculated by using $3d^{7}4s$ atomic configuration⁸ with lattice constants⁹ appropriate to 11°K, viz., $a = 6.2391$ a.u. and $c = 9.9316$ a.u. The exchange interaction was included in full Slater $\rho^{1/3}$ approximation. The LCAO interpolation method employed in our calculations consists essentially in assuming a tight-binding LCAO form for the one-electron wave function and parameterizing the Hamiltonian in terms of one- and two-center energy integrals,¹⁰ which are then determined by obtaining the best fit to the augmented-plane-wave (APW) eigenvalues at high-symmetry points in the Brillouin zone. Since scandium has two atoms per unit cell, the electronic structure was adequately represented by 18 basis functions, namely, one $s$ function, three $p$ functions of type $x$, $y$, $z$ times $f_{i}(r)$, and five $d$ functions of type $xy$, $yz$, $xz$, $\frac{1}{2}(x^{2} - y^{2})$, $(3z^{2} - r^{2})/(2\sqrt{3})$ centered on each atom. In the two-center approximation, the number of independent energy integrals¹⁰ reduces to 16. However, since Sc does not have an ideal hcp structure, 10 additional two-center energy integrals pertaining to the atoms out of basal plane were introduced. These parameters were then varied simultaneously using the techniques discussed by Connolly.¹¹ The rms error of the fit with 26 parameters for 200 eigenvalues calculated at 21 points in Brillouin zone was 5 mRy.

The quadratic interpolation scheme (QUAD) of Mueller et al.¹² was then used to calculate the energy eigenvalues and eigenvectors at a large number of points, to give the histogram representation of projected and total density of states for the energy of interest. To facilitate the application of QUAD scheme to a hcp Brillouin zone, we expanded
the irreducible wedge of the Brillouin zone to make a bigger orthorhombic sector, as shown in Fig. 1, such that it has also the point-group symmetry of hcp structure. This sector is then divided into small cubes, and the eigenvalues and eigenvectors calculated at 27 points lying at the corners and the centers of faces of each cube and are then used to get a quadratic expansion of energy eigenvalues, and eigenvectors in terms of the vector \( \mathbf{k} \), \( \mathbf{K} \), being the center of the cube. The expansion coefficients are then used in conjunction with the Monte Carlo techniques to calculate the total and projected density of states for various symmetries as follows: We assume that the wave function at the point \( \mathbf{k} \) for the 4th band is given by

\[
\psi_{i}(\mathbf{r}) = \sum_{\mathbf{k}} a^*_{\mathbf{k}}(\mathbf{r}) \psi_{\mathbf{k}}(\mathbf{r}),
\]

\( \psi_{\mathbf{k}}(\mathbf{r}) \) being the basis function in tight-binding representation for symmetry \( \rho \), and the sum over \( \rho \) runs over the above-mentioned 18 basis functions. The projected density of states \( N_i(E) \) for the symmetry \( i \) is given by

\[
N_i(E) = \frac{1}{(2\pi)^3} \sum_n \int d\mathbf{k} \delta(E_n^\mathbf{k} - E) \sum_{\mathbf{k}} |a^*_{\mathbf{k}}(\mathbf{r})|^2,
\]

where the summation over \( n \) extends over all the basis functions belonging to the symmetry \( i \).

We shall consider now the calculation of the magnetic susceptibility \( \chi_{\text{pol}}(T) \) for polycrystalline scandium, and its temperature variation. We have assumed here that the contributions due to all other terms except those due to the exchange-enhanced Pauli spin susceptibility \( \chi^p_s(T) \), the Van Vleck orbital susceptibility \( \chi^o_{\text{orb}}(T) \), and the diamagnetic susceptibility \( \chi^d_{\text{diam}} \) (due to the orbital motion of core and conduction electrons) are negligible. Thus \( \chi_{\text{pol}}(T) \) is given by

\[
\chi_{\text{pol}}(T) = \chi^p_s(T) + \chi^o_{\text{orb}}(T) + \chi^d_{\text{diam}},
\]

where

\[
\chi^o_{\text{orb}}(T) = \frac{1}{3} [\chi^o_{\text{VV}}(T) + 2 \chi^p_{\text{VV}}(T)]
\]

and

\[
\chi^p_s(T) = \chi_s(T)/[1 - \alpha \chi_s(T)].
\]

Here \( \chi^o_{\text{VV}}(T) \) and \( \chi^p_{\text{VV}}(T) \) are the Van Vleck orbital susceptibility along the \( c \) and \( a \) crystallographic axes, and \( \chi_s(T) \) is the Pauli spin susceptibility. The molecular-field coefficient parameter \( \alpha \) proposed by Stoner is related to the Stoner enhancement factor \( D \) through the relation

\[
D = 1/[1 - \alpha \chi_s(0)].
\]

The parameter \( \alpha \) is in principle a function of temperature, but since we are considering the variation of \( \chi_{\text{pol}}(T) \) over a small range of temperature, and the variation of \( \alpha \) with temperature is not known, we have assumed it to be independent of temperature, determined from the experimental value of \( \chi_{\text{pol}}(T) \) at some temperature \( T \).

The Pauli spin susceptibility is given by

\[
\chi_s(T) = \mu^2 \frac{\partial}{\partial E} \int_0^\infty \frac{\nu(\epsilon) d\epsilon}{1 + \exp[(\epsilon - \xi)/kT]} - \frac{\mu^2}{kT} \int_0^\infty \nu(\epsilon)\gamma(\epsilon)[1 - f(\epsilon)]d\epsilon,
\]

where \( \xi \) is the chemical potential, \( \nu(\epsilon) \) is the total DOS per atom, \( f(\epsilon) \) is the Fermi function, and \( \mu \) is the Bohr magneton. Owing to the critical position of the Fermi level, we evaluated this integral accurately by interpolating the total DOS between histogram boxes using cubic, quadratic, and linear interpolation methods, and found the same results. We found that the position of the peak in \( \chi_s(T) \) is a very sensitive function of Fermi energy and changes by 2 K if the Fermi level shifts by as little as 0.1 mRy.

The Van Vleck orbital susceptibility \( \chi^o_{\text{VV}} \) and \( \chi^p_{\text{VV}} \) were calculated using the Kubo and Obata formula,

\[
\chi^o_{\text{VV}}(T) = \mu^2 \int \frac{d\mathbf{k}}{(2\pi)^3} \sum_{\mathbf{k}} \left( \frac{f(E_r(\mathbf{k})) - f(E_r(-\mathbf{k}))}{E_r(\mathbf{k}) - E_r(-\mathbf{k})} \right) \langle \psi_{\mathbf{k}}^* | L_{\mathbf{r}} | \psi_{\mathbf{k}} \rangle \langle \psi_{\mathbf{k}}^* | L_{\mathbf{r}} | \psi_{\mathbf{k}} \rangle,
\]

where

\[
\langle \psi_{\mathbf{k}}^* | L_{\mathbf{r}} | \psi_{\mathbf{k}} \rangle = \sum_{\alpha} a^*_{\mathbf{k}}(\mathbf{r}) a_{\mathbf{k}}(\mathbf{r}) \langle \phi_{\mathbf{k}}^\alpha | L_{\mathbf{r}} | \phi_{\mathbf{k}}^\alpha \rangle,
\]

and

\[
\langle \psi_{\mathbf{k}}^* | L_{\mathbf{r}} | \psi_{\mathbf{k}} \rangle = \sum_{\alpha} a^*_{\mathbf{k}}(\mathbf{r}) a_{\mathbf{k}}(\mathbf{r}) \langle \phi_{\mathbf{k}}^\alpha | L_{\mathbf{r}} \phi_{\mathbf{k}}^\alpha \rangle.
\]
The matrix elements of the operators $L_x$ and $L_y$ between various basis functions can be calculated analytically, if one neglects the overlap between the neighboring atoms. In this approximation $\varphi_{\mathbf{r}}(\mathbf{r})$ becomes independent of $\mathbf{k}$ and reduces to an atomic orbital function of symmetry $p$ represented by $|p\rangle$ say. We note that the matrix elements involving $s$ functions, or between basis functions of different $l$ symmetry vanish identically. The nonvanishing matrix elements are listed below:

$$
\langle yz | L_x | xz \rangle = -\langle xz | L_s | yz \rangle = i,
$$

$$
\langle \frac{1}{2} (x^2 - y^2) | L_y | xy \rangle = -\langle xy | L_s | \frac{1}{2} (x^2 - y^2) \rangle = 2i,
$$

$$
\langle xz | L_y | xy \rangle = -\langle xy | L_s | xz \rangle = i,
$$

$$
\langle \frac{1}{2} (x^2 - y^2) | L_x | yz \rangle = -\langle yz | L_s | \frac{1}{2} (x^2 - y^2) \rangle = i,
$$

$$
\langle (3z^2 - r^2)/2\sqrt{3} | L_x | yz \rangle = -\langle yz | L_s | (3z^2 - r^2)/2\sqrt{3} \rangle = i\sqrt{3},
$$

$$
\langle z | L_y | y \rangle = -\langle y | L_s | z \rangle = i,
$$

$$
\langle y | L_x | x \rangle = -\langle x | L_s | y \rangle = i.
$$

The integrand in the expression for $\chi_{\nu\nu}$ and $\chi_{\nu\nu}'$ involving the above matrix elements and appropriate energy denominators was exactly computed at 1331 points in the $\frac{1}{4}$ of the Brillouin zone and then the quadratic interpolation scheme, in conjunction with the Monte Carlo sampling techniques, was used to compute the integral. The temperature variation of the orbital susceptibility was calculated using the explicit temperature dependence of the Fermi function. We also calculated $\chi_{\nu\nu}$ and $\chi_{\nu\nu}'$, without considering the contribution from the basis functions of $p$ ($l = 1$) symmetry. We compare our results with those of Ross et al.\textsuperscript{17} based on the analysis of NMR experiments. In the NMR analysis, the neglect of the $p$ density of states is justified due to the small $p$ hyperfine field relative to that of the $s$ electrons, and to the small $p$ density of states at the Fermi surface relative to that of the $d$ electrons. Thus accordingly we define the fractional $s$ character at the Fermi surface to be

$$
\mu_s = \frac{N_s(E_F)}{N_s(E_F) + N_d(E_F)},
$$

$N_s(E_F)$ and $N_d(E_F)$ being the projected $s$ and $d$ density of states at the Fermi energy $E_F$.

We have also calculated the average values of fractional admixture coefficients\textsuperscript{17} in the density of states for the symmetries $E'$, $A_1'$, and $E'''$ (alternately denoted by $\Gamma_3$, $\Gamma_6$, and $\Gamma_8$, respectively, in Herring's notation) appearing in the analysis of magnetic susceptibility of Ross et al. by calculating the projected density of states for these symmetries.

### III. RESULTS

The energy band structure of scandium along high-symmetry directions obtained from the interpolation method using parameters given in Table I is shown in Fig. 2. The solid circles represent the APW eigenvalues. The rms error of the least-square fit is of the order of 5 mRy, and since only the low-lying bands are used to get the best fit to the \textit{ab initio} calculations, the agreement with the interpolation-scheme results is better for low-lying bands. Here the Fermi energy lies in a region where the energy bands are extremely flat, as a result of which the shape of the Fermi surface is highly sensitive to the position of the Fermi energy. This is particularly evident along the AL and HL symmetry directions. The total–density-of-states and $d$–density-of-states curves shown in Fig. 3 also indicate similar features. The Fermi energy which was obtained by integrating the total–density–of–states curve to yield three electrons per atom, lies exactly in the histogram box of width 1 mRy at a peak in the total– and $d$–DOS curve. Although the accuracy of band structure calculations is limited to a few millirydbergs, the

</table>
error in the position of the Fermi level obtained this way can be much smaller by virtue of the very fact that it is so close to the peak. As shown below this critical position of the Fermi energy is responsible for the unusual magnetic properties of scandium. The large value of the fractional d character $\rho_d$ at Fermi energy is in agreement with the experimental data on the magnetic susceptibility and the nuclear magnetic resonance\textsuperscript{17} as shown in Table II. However, the projected p density of states at the Fermi energy was found to be about 20% of the total density of states, a rather large quantity. The fractional admixture coefficients $F^{\Gamma(\Lambda\rho)}$, $F^{\Gamma(\pi\pi')}$ and $F^{\Gamma(\pi')}$\textsuperscript{30, 24, 21, 2} and 15.2, respectively, in units of $(1 - \mu) \times 10^6$ at the Fermi energy also differ considerably from their estimated values by Ross \textit{et al.}\textsuperscript{17}

We shall compare now our results for magnetic susceptibility with experiments. The susceptibilities $\chi_{\pi\pi}$ and $\chi_{\pi\pi'}$ calculated using the explicit temperature dependence of the Fermi function were found to be rather insensitive functions of temperature with values of about $2.69 \times 10^{-6}$ and $2.92 \times 10^{-6}$ emu/g, respectively. Compared to Spedding and Croat’s reported value of $\chi_{\pi\pi} \sim 0.42 \times 10^{-6}$ emu/g for $T > 1.5$ K decreasing to $-0.19 \times 10^{-6}$ emu/g for $T \sim 60$ K, we obtain $\chi_{\pi\pi} \sim \chi_{\pi\pi'}$ to be about $0.21 \times 10^{-6}$ emu/g for $T \sim 50$ K decreasing to $0.21 \times 10^{-6}$ emu/g for $T \sim 300$ K. The discrepancy between our calculations and the experimental results for $\chi_{\pi\pi} - \chi_{\pi\pi'}$ could be attributed to additional contributions coming from the anisotropic mass tensor when spin-orbit coupling is considered (which has been neglected in the present study).

Of special interest in these calculations is the role of the p character of wave function at the Fermi surface. While the p contribution to the total density of states as mentioned before is about 20%, that to the values of $\chi_{\pi\pi}$ or $\chi_{\pi\pi'}$ individually is about 0.3% and the contribution to the difference $\chi_{\pi\pi} - \chi_{\pi\pi'}$ is approximately 3ting. Another interesting result of our calculations is that the value of $\chi_{\pi\pi} - \chi_{\pi\pi'}$, calculated using the expression by Ross \textit{et al.},\textsuperscript{17} involving the average values of the fractional admixture coefficients $F^{\Gamma(\Lambda\rho)}$, $F^{\Gamma(\pi\pi')}$, and $F^{\Gamma(\pi')}$, has not only the wrong magnitude but also the wrong sign. Thus it appears very essential to evaluate the integral for $\chi_{\pi\pi}$ and $\chi_{\pi\pi'}$ exactly. The results for polycrystalline susceptibility $\chi_{\text{pol}}(T)$ assuming $\alpha$ to be independent of temperature, are plotted in Fig. 4 along with the experimental results of Spedding and Croat.\textsuperscript{1} Here we assumed $\chi_{\text{dam}} = 0.93 \times 10^{-6}$ emu/g, as obtained by Mandelsohn \textit{et al.},\textsuperscript{18} and used Eqs. (3) and (4) with the experimental value of $\chi_{\text{pol}}$ at 20 K, to estimate the value of $\alpha$ to be 0.5558 $\times 10^6$ g/emu. The position and the height of the peak in $\chi_{\text{pol}}(T)$ is in good agreement with the low-temperature data but at high temperatures $\chi_{\text{pol}}(T)$ is larger than the experimental value, which can be explained by the decrease in the mean molecular-field coefficient parameter $\alpha$ due to increased spin fluctuations at higher temperatures.

Finally we shall consider enhancement of the density of states due to both the electron-phonon interaction and the spin fluctuations, and its relation to the absence of superconductivity in Sc. The enhancement factor $\lambda$ defined by

$$1 + \lambda = N_g / N_B,$$

where $N_g$ is the enhanced total DOS and $N_B$ is the

**FIG. 4.** The variation of magnetic susceptibility of polycrystalline Sc with temperature. For comparison the results of Spedding and Croat on polycrystalline sample 4–155(poly) are plotted.

The bare DOS, can be written as

\[
\lambda = \lambda_{sp} + \lambda_{se} + \lambda_{spin}
\]

where \( \lambda_{sp} \) is the enhancement factor due to the electron-phonon interaction and is responsible for the superconducting properties of materials. \( \lambda_{spin} \) is the contribution due to the spin fluctuations or the electron-paramagnon interaction, and \( \lambda_{se} \) is due to the electron-electron interaction. Generally \( \lambda_{se} \) is very small compared to \( \lambda_{sp} \) and \( \lambda_{spin} \) for transition metals. The total density of states \( N_\beta \) obtained from our band-structure calculations is 26.73 Ry\(^{-1}\) atom\(^{-1}\). The enhanced density of states \( N_{\beta\alpha} \) obtained from the electronic specific-heat coefficient \( \gamma(0) \) at 0 K, is 60.2 Ry\(^{-1}\) atom\(^{-1}\). Thus the enhancement factor \( \lambda \) from our calculations is about 1.25. The enhancement factor due to the electron-phonon interaction \( \lambda_{sp} \), estimated using the value of density of states \( N_{\beta\alpha} (= 45.0 \text{ Ry}^{-1} \text{ atom}^{-1}) \) obtained from the extrapolation of the electronic specific-heat coefficient \( \gamma(T) \) at high temperatures to 0 K is about 0.3. This value of \( \lambda_{sp} \) when substituted in the McMillan’s equation for \( T_c \), the superconducting transition temperature, gives \( T_c \approx 0.005 \text{ K} \) and is thus consistent with the
observed absence of superconductivity in scandium. This shows that the virtual scattering of electrons on the Fermi surface via spin fluctuations plays a very important role in enhancing the density of states in addition to that due to the electron-phonon interaction for Sc. In fact, the value of \( \lambda_{op} \) \((=1.24)\) obtained from the relation\(^{20}\) \( \lambda_{op} = 4.5 \ln(1 - T) - 1 \), where \( T = \frac{1}{2} \alpha \chi_0(0) \), with our estimated value of \( \alpha = 0.5556 \times 10^6 \text{ emu/g and } \chi_0(0) = 1.4138 \times 10^{-6} \text{ g/emu} \), shows that almost all the observed enhancement of the density of states in low-temperature specific-heat measurements is due to the spin fluctuations, and \( \lambda_{op} \) is indeed very small.

The main conclusion from these calculations is that the peak in the susceptibility of scandium can be explained successfully only if we assume that the Fermi level for Sc is trapped within a sharp peak in the density-of-states curve. The value of the Pauli spin susceptibility derived from the itinerant electron model and the molecular-field parameter \( \alpha \) estimated from the magnetic susceptibility measurements can explain the observed absence of superconductivity in scandium. The calculated anisotropy in the susceptibility measurements, the projected density of states are also consistent with the experiments. Thus one can safely believe in the itinerant character of \( d \) electrons in transition metals.

ACKNOWLEDGMENTS

I am highly indebted to Professor S. K. Sinha for many enlightening discussions and guidance. I would like to thank Professor A. J. Freeman for supplying the augmented-plane-wave computer program and to Dr. M. H. Mueller for supplying the lattice constants.

8Our previously reported (Ref. 5) relativistic band-structure calculations of Sc, with 3d4s1 atomic configuration showed that the integrated \( d \) density of states up to the Fermi energy is approximately twice as large as that compared to the \( s \) density of states, thus establishing that Sc prefers the configuration 3d4s1 rather than 3d4s2 in crystal. The relativistic effects were also found to be negligible.
